Abstract. Actinomycosis in the pelvic region is an uncommon diagnosis. This infection is caused by Actinomyces israelii, a gram-positive anaerobic saprophyte bacterium that is a normal inhabitant of the upper intestinal tract in humans. Pelvic actinomycosis is difficult to diagnose pre-operatively and is diagnosed, in most cases, accidentally. Actinomycosis can mimic pelvic and abdominal malignancies. A case report of a 35-year-old female patient with a fixed pelvic mass is presented and the diagnosis and treatment of pelvic actinomycotic inflammatory disease in relation to ovarian cancer are discussed. Clinicians should be aware of this rare infection to spare women potential morbidity from excessive surgical procedures.

Despite the broad use of tumor markers, sonography and computerized tomography, the differentiation between benign and malignant pelvic masses is still a clinical challenge. Accurate differential diagnosis is necessary because the treatment strategies vary greatly. A case of actinomycotic inflammatory disease, which was misdiagnosed as an advanced ovarian cancer, is reported.

Case Report

A 35-year-old female, gravida 1, para 1, was referred with suspected ovarian cancer from an external hospital where she had received operative treatment 3 weeks previously. She complained of abdominal pain, increasing abdominal girth, adnexal masses, diarrhea, fever of 38.5°C and a 10-kg weight loss over the preceding 4 months. Additionally, hydronephrosis of the right kidney was diagnosed. In the history of the patient there had been no previous surgery or other severe disease. An intrauterine device (IUD) had originally been placed 9 years previously and had been changed every 2 years since then. Two months prior to admission, the IUD had been removed.

An exploratory laparotomy was performed, but was complicated by extreme adhesions, fibrosis (frozen pelvis) and cystic changes of the ovaries. Despite the fact that biopsies of the peritoneum showed no signs of malignancy, a diffuse peritoneal carcinomatosis was suspected. After receiving a right nephrostomy, in recovery, the patient was referred to our clinic for completion of the surgical management of her supposed advanced ovarian cancer. At this time the patient was afebrile. On pelvic examination, there was a solid, tender and fixed pelvic mass extending to both pelvic walls and to the posterior sacral region. The assessment of the lower abdomen by transvaginal and transabdominal sonography showed solid hypoechoic-appearing adnexal masses with cystic components and without blood flow. Normal ovaries were not detectable. Ascites was not detected either in the pouch of Douglas or in the upper abdomen. The findings did not allow for the differentiation between a benign or malignant process (Figures 1a, 1b). The laboratory data revealed a slight leukocytosis of 11.9x10^9/µl, CRP (acute infection-related protein) of 4.1 g/dl (normal range <0.6 mg/dl) and hemoglobin of 9.8 g/dl. The tumor marker CA-125, at 49 U/ml, was slightly increased (normal range <35 U/ml).

A pre-operative cystoscopic placement of ureteral stents was followed by a median laparotomy. After lysis of the intestinal adhesions and careful mobilization of the colon, small bowel and sigmoid colon, severe bilateral tubo-ovarian abscesses were revealed. All the pelvic structures were covered with marked fibrosis. A bilateral salpingo-oophorectomy was performed. Drainage (easy-flow) was placed in the pelvic region.

The histopathological examination showed no evidence of malignancy, but the presence of sulfur granules
characteristic of *Actinomyces israelii* and led to the diagnosis of an extensive actinomycotic involvement of both ovaries and fallopian tubes (Figures 2a, 2b).

Immediately, the patient received a combination of Ampicillin and Sulbactam intravenously at a dose of 3 x 1.5 g/day for 2 weeks, followed orally for another 4 weeks. The post-operative period was without complications. The drain was removed after 5 days. After 8 days, the ureteral stents were removed and no hydrenephrosis was detected. Fourteen days after surgery, the pelvic examination showed complete resolution of the induration and masses in the pelvis and the patient was discharged without any complaints. She is still without any symptoms 2 years after surgery.

**Discussion**

*Actinomyces israelii*, a filamentous, gram-positive bacillus, is a part of the microflora of the human oral cavity. *Actinomyces israelii* can not penetrate through the normally intact mucosal barrier (1). Actinomycotic disease is a rare diagnosis, the overall incidence being 1:100,000 to 1:300,000 annually, with rates 3 times as high for men as women (1). Most cases are seen in adolescents and middle-aged adults (1). Its manifestation in the pelvic region is rare. Furthermore, the incidence of IUD-associated cervicovaginal actinomycosis has been shown to be between 8 and 16% in most studies (2-4). Although rarely diagnosed, its important should be considered in the differential diagnosis of ovarian cancer (2). Fiorino reviewed the literature in 1996 and found 92 cases in 63 reports describing actinomycotic pelvic inflammatory disease simulating ovarian cancer (5). We analyzed an additional 7 reports of 8 patients published since 1996 (6-12).

Different symptoms can be compared between actinomycotic inflammatory disease (5-10) and ovarian cancer (13, 14) and the most common of these are summarized in Tables I and II, together with the corresponding difficulties in clinical discrimination.

It is clear from the database that findings of *Actinomyces israelii* can easily be confounded with ovarian carcinoma. Especially in women with an IUD, this differentiation should be made before laparotomy, as Chatwani and Amin-Hanjani showed in their study including 1,520 women with IUDs (2). In this study, the colonization rate increased with the duration of IUD use, reaching an overall colonization rate of 11.4%. These authors suggested that patients with IUDs should undergo annual cytological smears. Recently, Marwah and colleagues presented an unusual case of ovarian actinomycosis of a patient without an IUD (19).

Various other predisposing factors are discussed in the literature based on retrospective data and with limited evidence: neoplasia, dental caries, gastrointestinal tract perforation (necrosis), abdominal surgery, orogenital sex, compromised immune status (12).

Since the symptoms of both ovarian cancer and infection with *Actinomyces israelii* are very similar, non-invasive differentiation of the two diseases is particularly limited and can be achieved pre-operatively in only 10% of the cases. Some authors reported a diagnosis using ultrasound-guided biopsies (15). Lee and co-workers described a case using transcutaneous computerized tomography-guided core needle biopsy in the diagnosis of pelvic actinomycosis (11). Culture methods are often too slow and relatively insensitive for the definitive diagnosis of infection with *Actinomyces israelii* (7). In *vivo* culture is difficult and requires microaerophile conditions and special culture media. Only 25% of actinomycotic cultures show positive results after a period of 3 to 4 weeks (1).

For solid-appearing masses and in early ovarian malignancy, Doppler sonography facilitates the pre-operative discrimination between benign and malignant processes (16). Adding color Doppler to conventional transvaginal sonography produces a specific and positive predictive value higher than that of conventional sonography alone in differentiating adnexal masses and can give additional information (17). In our case, however,
transabdominal and transvaginal gray scale imaging and the use of color Doppler were not helpful in differentiating the bilateral adnexal masses. In the case of persisting symptoms, laparoscopy or laparotomy should be performed. Surgical intervention should be limited to relieving obstructive symptoms and to removing necrotic tissues. To prevent post-operative fistulas, broad dissection of the intestines, ureter and bladder should be avoided. Drainage of pelvic

abscesses is the most beneficial procedure and helpful in most cases (4, 18).

The therapy of choice consists of surgical resection of the inflammatory, infected tissue and long-term penicillin-based antibiotic therapy. For a patient with an IUD, *Actinomyces israelii* in the cervico-vaginal smear, together with any of the symptoms mentioned above, primary antibiotic therapy is preferred.

**Conclusion**

Pelvic actinomycosis is a rare inflammatory disease which mimics ovarian cancer. Differentiation is difficult, but a history of IUD use, *Actinomyces israelii* detection and absence of serum tumor markers should prompt the diagnosis of actinomycosis. To avoid invasive detection methods, all aspects of differentiation, including laparoscopy
with biopsies, should be considered in cases in which the diagnosis remains unclear or when symptoms persist.
