Abstract. Background: Phytoestrogens have controversial effects on hormone-dependent tumors. Herein we investigated the effects of parsley root extract (PCE) on DNA synthesis performance, metabolic activity and cytotoxicity in malignant and benign breast cells. Materials and Methods: The PCE was prepared and analyzed by mass spectrometry. MCF7 and MCF12A cells were incubated with various concentrations of PCE and analyzed for DNA synthesis performance, metabolic activity and cytotoxicity by BrdU proliferation, MTT and LDH assays, respectively. Results: PCE was found to contain a substantial ratio of lignans. At a concentration range of 0.01 μg/ml-100 μg/ml the LDH assay analysis showed no significant cytotoxicity of PCE in both cell lines. However, at 500 μg/ml PCE’s cytotoxicity was well over 70% of total cell population in both cell lines. According to the BrdU proliferation assay analysis, PCE demonstrated significant DNA synthesis inhibition of up to 80% at concentrations of 10, 50, 100 and 500 μg/ml in both cell lines. Based on the MTT assay analysis, only at a concentration of 500 μg/ml, PCE demonstrated a statistically significant inhibition of cellular metabolic activity of 63% in MCF7 and 75% in MCF12A of their respective normal capacity. Conclusion: PCE showed antiproliferative effects in MCF7 and MCF12A cells. Further investigation is required to determine whether this effect can be solely attributed to its phytoestrogens.

Key Words: Petroselinum crispum, estrogen receptor, breast cancer, MCF7, MCF12A.
and for detoxification. It contains a substantial amount of vitamin C and constitutes as a good source of iron, potassium, calcium, manganese and folic acid (12, 13). The active compounds identified in *Petroselinum crispum* are phenolic compounds, flavonoids (particularly apiigenin, apin and 6-acetylapin) and essential oils – mainly myristicin and apiole (14). Also notable are the photosensitizing furanocoumarines bergapten and isorhapontigenin in the root that increase the photosensitivity of the skin and are associated with an increased incidence of malignant melanoma (15).

Research on the presence of phytoestrogens in parsley root has attracted little attention. Only the research team led by M. Yoshikawa demonstrated that the methanolic extract from the aerial parts of *Petroselinum crispum* showed potent estrogenic activity, which was equal to that of isoflavone glycosides from soybean. In addition, they demonstrated that the methanolic extract of parsley, apiin and apigenin restored the estrogenic activity, which was equal to that of isoflavone glycosides from soybean.

Due to the interesting characteristics of parsley root described above, the current *in vitro* study aims to identify the molecular chemical composition of parsley root extract (PCE) by mass spectrometry and to evaluate the potential phytoestrogen effects of PCE in terms of DNA synthesis performance (BrdU proliferation assay), metabolic activity (MTT assay) and cytotoxicity (LDH assay) on MCF7 breast cancer and MCF12A benign breast cell lines. Furthermore, the receptor status of MCF7 and MCF12A cells will be determined by immunohistochemical staining of ERα, ERβ and PR.

Materials and Methods

**Origin of the PCE.** The parsley root (*Petroselinum crispum* subsp. tuberosum) was grown, harvested and obtained commercially in 2011 in Mecklenburg-Western Pomerania, at vegetable farming Hofer Neubrandenburg.

**Preparation of the PCE.** The lignan-isolations were prepared as previously described (17-18). Deep frozen (~20°C) parsley root (40 g) was cut into pieces of 5 mm. The pieces were ground in a mortar with liquid nitrogen and extracted under reflux with 360 ml methanol (methanol 99.5%; Roth, Karlsruhe, Germany) in a water bath at 75°C. The extract was suspended in 10 ml of distilled water and partitioned with 16 ml ethyl acetate (five times) to give on evaporation of the ethyl acetate soluble residue. After cooling the sample, the methanolic extract of parsley, apiin and apigenin restored the weight of the extract it was dissolved with 96% ethanol (Roth, Karlsruhe, Germany) in an ultrasonic bath (Ultrasonics (300/H); Omnilab, Bremen, Germany) under uniform reduction of pressure from 350 mbar to approximately 100 mbar. Adhering extract to the wall of the round bottomed flask was removed with 10 ml distilled water and then dissolved in an ultrasonic bath (Ultrasonics (300/H); Omnilab, Bremen, Germany) and extracted 5 times with 16 ml ethyl acetate (99.5%; Roth, Karlsruhe, Germany) in a 50 ml Falcon tube. This process leads to significant phase separation into a lower, denser phase (water phase), and an upper phase (lipid phase, containing lignans). The upper phase was carefully aspirated by a Pasteur pipette and transferred to a 50 ml round bottomed flask. The sample was again evaporated in a rotational evaporator at 45°C, under a uniform decrease in pressure from 400 mbar to about 250 mbar. The evaporated extract was dried overnight using a desiccator (with dried silica). To determine the net weight of the extract, the difference of the tare of the round bottom flask and the weight of the flask with dried extract was made (MC1 Analytic scale AC120S; Sartorius GmbH, Göttingen, Germany). The extract was stored protected from light in a refrigerator at 4°C.

In order to verify the previously reported increased phytoestrogen concentration in PCE the molecular-chemical composition of the extract was further analyzed by pyrolysis-field ionization mass spectrometry by using a LCQ-Advantage (Thermo Finnigan’s city & state). The peaks were identified by ion trap technology on ESI mode. The source voltage was set at 4.5 kV while the mass detection range was 150-2000 amu.

**Creation of different PCE concentrations.** After determining the weight of the extract it was dissolved with 96% ethanol (Roth, Karlsruhe, Germany) in an ultrasonic bath (Ultrasonics (300/H); Omnilab, Bremen, Germany) and the concentration of 100 mg/ml was determined (stock solution). For the following test series, 7 dilutions (excl. the stock solution) were set at the concentrations of 50,000 - 10,000 - 5,000 - 1,000 - 100 - 10 - 1 μg/ml. The extract was then further diluted, 1:100 giving the final concentrations 500 - 100 - 50 - 10 - 1 - 0.1 to 0.01 μg/ml. The dilutions were frozen at ~85°C.

**Cell lines.** The ER-positive, malignant breast cancer cell line MCF7 and the ER-positive, benign breast cell line MCF12A were used. Both cell lines were obtained commercially from the American Type Culture Collection (ATCC) and for further use in 1.5 ml culture medium (PAA, Germany) + 10% DMSO + 20% fetal calf serum (fetal bovine serum, Biochrom, Germany) stored at ~180°C.

**Cell culture.** After slow thawing, the cryopreserved cells were washed by 5 ml cell type-specific medium. For MCF7 cells, DMEM, high Glucose 4.5g (PAA, Germany), for MCF12A, Ham’s F12 medium (PAA Germany) were used. For this, the cell suspension was carefully pipetted into 15 ml tubes and diluted with 5 ml culture medium. After vortexing and subsequent centrifugation for 5 min at 1000 rpm (centrifuge Universal 320R Hettich Zentrifugen, Germany), the supernatant was discarded. The cells were re-suspended in 5 ml culture medium, transferred to 25-cm² cell culture flasks (Biochrom, Germany) and incubated at 37°C, 5% CO₂ for 2-3 days. At a confluence rate of 80%, the medium was changed and the cells were split in a larger culture flask (75 cm², 150 cm², Biochrom, Germany). The cells were rinsed with phosphate buffered saline (PBS: Dulbecco’s PBS powdered buffer, without Ca & Mg, PAA, Germany) to remove the upper layer of protein on the cells which would prevent an effective engagement of the trypsin before incubating them with trypsin (10%, trypsin EDTA, PAA, Germany) for 5 min at 37°C. The reaction was stopped by adding DMEM (DMEM High Glucose (4,5g) +L-glutamin; without phenol red, PAA, Germany). The complete detachment of the cells was monitored by light microscopy. Following centrifugation for 5 min at 1000 rpm, the supernatant was discharged and cells were re-suspended in 5 ml cell-specific medium. For MCF7,
10% FKS, (PAA, Germany), for MCF12A, 10% Horseserum, (SIGMA, Germany) were used. Penicillin/Streptomycin 0.2% (PAA, Germany) and Amphotericin B 0.5% (PAA, Germany) were added to both cell lines.

Cell counting. Despite the fact that cell proliferation depends on the cell concentration and that cells need contact with neighboring cells in order to grow, when cell count is elevated nutrient shortages occur that may lead to apoptosis. The optimal cell concentration, determined by previous studies was set at 5 × 10⁵ cells/ml (19). Most cell vitality assays that allow cell count determination are based on the change in membrane permeability of dead cells. Vital cells are impermeable for dyes such as trypan blue. Therefore, only the colorless cells are counted in phase contrast microscopy. To cell count, 20 μl of the cell suspension were diluted with 340 μl of cell culture medium and then combined with 20 μl trypan blue (corresponding dilution 1:20). To avoid trypan blue staining of intact cells, prompt counting was done. For this, about 20 μl of the probe was added to both sides of a Bürker cell counting chamber. Counting was done under a phase contrast microscope at a magnification of 100x.

General and statistical considerations. In all tests, a positive control (17β-estradiol, E2) and a negative control (tamoxifen, TAM) were carried along with the extract in different concentrations levels. Preliminary tests done using the same workgroup yielded optimal concentrations for E2: 10⁻⁹ mol/l and TAM: 10⁻⁴ mol/l. All calculations of the results were performed using Microsoft Excel considering the standard deviation. Statistical analysis was performed using the t-test. Each observation with 0.05 was considered as statistically significant.

Measurement of cytotoxicity by LDH assay. The LDH assay (Roche, Mannheim, Germany) was performed in accordance with the manufacturer’s instructions. Best results were achieved after incubation of treated cells (5 × 10⁵ cells/ml) for 24 h in the absence (controls: TAM, E2) or the presence of PCE at different concentrations. Maximum LDH release (high control) was determined by incubating cells with Triton X-100 at 1% final concentration (Ferak, Berlin, Germany). Untreated cells were used to determine spontaneous LDH release (low control). After incubation, cells were gently centrifuged for 5 min 1,000 rpm. Subsequently, cell-free supernatants were carefully removed and transferred into a new 96-well microplate. Supernatants were mixed 1:1 with freshly prepared reaction mixture and incubated protected from light for 30 min at room temperature. The principle of the assay is based on a LDH/diaphorase coupled reaction with creation of a red colored formazan. Absorbance of the color was measured at 490 nm (620 nm wave length was used as a reference).

Proliferation measurement: MTT assay. Cell proliferation was analyzed using an MTT-kit according to the instructions of the manufacturer (Roche, Germany). After incubation of treated cells (5 × 10⁵ cells/ml) for 24 h in the absence (controls: TAM, E2, N2) or presence of PCE at different concentrations, MTT labelled reagent was added to each well in a final concentration of 0.5 mg/ml. Subsequently, cells were incubated under culture conditions for 4 h. During this time the metabolic active cells transformed the yellow tetrazolium salt MTT to purple colored formazan crystals. After addition of the solubilization solution the plates were incubated overnight in a humidified atmosphere at 37°C. With a microplate reader (Model 680, Bio-Rad, Hercules, CA, USA) the color intensity was measured at 570 nm using a reference wave length of 650 nm.

BrdU proliferation-assay. Cell proliferation was analyzed with a 5-bromo-2'-deoxy-uridine (BrdU) labelling and detection kit (Roche, Germany) according to the instructions of the manufacturer. MCF7 and MCF12A cells (5 × 10⁵ cells/ml) were grown in 96-well tissue culture plates for 24 h in the absence (controls: TAM, E2, N2) or presence of PCE at different concentrations. After labelling with BrdU for 3 h, the cells were fixed and BrdU incorporation into DNA was measured by an ELISA technique. Cellular proliferation inhibition is expressed in relation to controls (100%±SD).

Immunohistochemical staining for the ERα, ERβ and PR. For immuno-detection of the steroid receptors ERα, ERβ and PR, the Vectastain R Elite ABC-kit (Vector Laboratories, USA) was used according to manufacturer’s protocol. The slides were first air dried, rinsed in PBS for 5 min and then incubated with the ABC reagent for 4 h. During this time the metabolic active cells transformed the yellow tetrazolium salt MTT to purple colored formazan crystals. After addition of the solubilization solution the plates were incubated overnight in a humidified atmosphere at 37°C. With a microplate reader (Model 680, Bio-Rad, Hercules, CA, USA) the color intensity was measured at 570 nm using a reference wave length of 650 nm.

Results

Immunohistochemistry. Expression of ERα, ERβ and PR receptors was evaluated in MCF7 and MCF12A cells (Figure 1). A negative control measurement was carried out in which instead of the primary antibody only secondary antibodies were added to show possible non-specific fluorescence signals. In both cell lines secondary antibodies were

negative, ruling out non-specific fluorescence signals. ERα demonstrated the strongest expression in both cell lines. ERβ and PR were less pronounced and comparable in intensity. MCF12A cells expressed lower levels of all receptors tested compared to MCF7 cells, which can be due to the benign nature of MCF12A and its lower metabolic activity and growth rate.

**LDH cytotoxicity assay.** The lactate dehydrogenase assay (LDH assay) indicates non-specific cytotoxic effects of the given extract that are measurable by enzymatic reactions of LDH. LDH is a cytosolic enzyme that is released from dead cells, making its concentration suitable as a quantitative indicator of cell death. As a positive control and to establish a reference value, cells were incubated with 1% Triton X-100, resulting in complete cell death. LDH activity in these controls was, therefore, set at 100%. Figure 2 shows that no significant cytotoxicity was observed at concentrations of 0.01 μg/ml to 100 μg/ml. Also estradiol (E2) did not cause significant cytotoxicity. However, significant cytotoxicity \((p<0.01)\) was caused by PCE at the concentration of 500 μg/ml in up to 80% of the cells of both cell lines (MCF7: 74.9±36.6%, MCF12A: 81.5%±14.7%), which is approximately equivalent to the effect observed with TAM (MCF7: 69.6%±22.6%, MCF12A: 98.7%±1.7, \(p<0.01\)).

**DNA synthesis performance: BrdU proliferation assay.** The bromodeoxyuridine (BrdU) proliferation assay provides insights into the DNA synthetic capacity of cells, making it a suitable marker for cell proliferation. During the DNA synthesis phase of the mitotic cycle, cells build the added base analogue BrdU into their genome. An antibody directed against BrdU catalyzes a colour reaction whose intensity directly correlates with the synthetic capacity of the cells. As a reference value, the negative control (N2, ethanol/DMSO) was set at 100%. Figure 3 compares proliferation rates of MCF7 and MCF12A cell lines incubated with the respective extract concentrations. PCE showed less pronounced antiproliferative effects in MCF12A cultures compared to MCF7, as more significant results were obtained using MCF7 cells. At PCE concentrations of 0.01, 0.1 and 1 μg/ml, little growth inhibition of MCF12A cells (max. 15%, at PCE 0.1 μg/ml: 85.5%±5.6%, \(p<0.01\)) was demonstrated. At the concentrations of 50 and 100 μg/ml the antiproliferative effect of PCE in MCF12A intensified, and statistical significance was demonstrated (50 μg/ml: 56.7%±13.8%, \(p<0.01\), 100μg/ml: 61.1%±14%, \(p=0.01\)). At 500 μg/ml extract concentration, significant inhibition of proliferation of 84.5% was noted (15.5%±11.7%, \(p=0.01\)) in MCF12A cells. In MCF7 cells, the PCE concentration of 0.01 μg/ml caused, compared to the concentrations of 1 and 0.1 μg/ml an increased, although not significant inhibition of cell proliferation of approximately 40% (61.77%±13.0%, \(p=0.08\)). Statistical significant inhibitions over 40% were demonstrated in MCF7 cells at the concentration levels of 10, 50, 100 and 500 μg/ml. The strongest inhibition of proliferation in MFC7 cells of approximately 80% was observed at a PCE concentration of 100 μg/ml (19%±2.7%, \(p<0.01\)).

**Cellular metabolic activity: MTT cell viability assay.** Metabolically-active cells have high activity of the mitochondrial enzyme succinate dehydrogenase, whose catalytic activity can be measured directly by a color reaction. High color intensities indicate increased metabolism and cell viability. As a reference value, the negative control N2 was set to 100%. In MFC7 and
MCF12A cell lines, both inhibitory and proliferative effects of PCE were demonstrated. At PCE concentration levels of 0.01 μg/ml to 10 μg/ml, weak effects in both cell lines were observed (Figure 4). Generally, metabolic activity was lower in MCF12A cells than in MCF7 cells, except at PCE concentration of 100 μg/ml (MCF12A: 155.7%±6.3%, p<0.01, MCF7: 144.9%±34.5%, p<0.01). Nevertheless, statistically significant results were found for all MCF12A concentrations, in contrast to MCF7 cells, where increased metabolism and significant results were achieved only at concentration levels of 100 μg/ml (proliferative effect, 144.9%±34.5%, p<0.01) and 500 μg/ml (inhibitory effect, 37.0%±9.3%, p<0.01). Strong, significant inhibition of cell
growth and metabolic activity was demonstrated in both cell lines at PCE concentration of 500 μg/ml, 37.0%±9.3% (p<0.01), cell viability for MCF7 cells and 24.4%±4% (p<0.01) for MCF12A cells. No influence on cell viability was observed by E2. However, Tamoxifen caused significant cytotoxicity and thus reduced metabolic activity in both cell lines (MCF7: 3.8%±0.9%, p<0.01, MCF12A: -14.0%±5.4%, p<0.01).

Pyrolysis/FI mass spectrometry. The results from pyrolysis mass spectrometry were compared with masses of different substance classes from public databases. In Figure 5, the main categories identified are presented with the respective percentage of the substance class from the total ion intensity. Untreated parsley root (PC) showed high carbohydrates and lipid fractions (18.6% and 12.3% respectively). Peptides and free amino acids are represented with 8.1%, as the third largest group. The extraction process caused a shift of the respective proportions of substances classes, resulting in less carbohydrates (2.1%), more lipids (18.2%) and more isoprenoids (14.1%) in PCE compared to PC. Together, the fractions monolignols, lignin dimers, lignans, flavones, isoflavones and other polyphenols (PHLM, LDIM, LIGNA, FLAVO, ISOFL, POLYO) represent the group of phytoestrogens (PC: 17%; PCE: 16.6%).

Discussion

In this study, we demonstrated that PCE has cytotoxic, inhibitory and anti-proliferative effects on cultures of both the benign MCF12A and cancer-derived MCF7 cell lines. The BrdU proliferation assay was used as the main method to detect inhibitory or stimulatory effects of PCE. To verify its accuracy, a LDH assay was performed to determine cytotoxicity. In both cell lines and at all PCE concentration levels with the notable exception of 500 μg/ml, no substantial increase in LDH activity was observed. In combination with the BrdU assay, these results suggest antiproliferative effects of PCE not related to cytotoxicity.

So far, the exact cytotoxic effects of PCE remain unknown. However, according to Dorman et al., it is likely that at high concentrations, toxicity is not mediated by caspase 3 apoptosis pathways but by strong pro-oxidative effects (20). Other possible apoptosis pathways are intrinsic signal molecules (cytochrome c, p53, p21) which can be activated by isoflavones, such as genistein (21, 22), apigenin (23) and lignans (24).

The BrdU assay showed little to no effect of PCE in both cell lines at low concentrations, but at higher concentrations (≥10 μg/ml) the following strong inhibitory effects: a reduction of cell proliferation by 42% in MCF12A (at 50 μg/ml) and by 80% in MCF7 cell lines (at 100 μg/ml). In further studies, the effect of PCE at the given different concentrations on ERα/ERβ/PR expression and the assessment by immunocytochemistry could clarify whether it is likely that MCF12A as a benign cell line is less sensitive to possible estrogenic properties of PCE due to a decreased receptor expression compared with malignant MCF7 cells.

A stronger inhibition was demonstrated in MCF12A cells at the concentration of 500 μg/ml, attributable to increased cytotoxicity and the associated cell loss. Paradoxically, in MCF7 cells, PCE demonstrated a weaker inhibition of cell proliferation at 500 μg/ml than at 100 μg/ml, despite cell death rates of up to 75%. Accordingly, the remaining intact cells (25%) would have to operate at a higher synthesis performance than, in this case, 90% of the cells at a PCE concentration of 100 μg/ml. Similar results were obtained by Moorghen et al. (25). They concluded that a higher proliferation rate compensates the cells under apoptosis (secondary effect). However, the low MTT assay values contradict this assumption. At a PCE concentration of 500 μg/ml, when high cytotoxicity was reported, low metabolic activity in both cell lines (max. 37%) was registered.

Interestingly, in MCF12A and MCF7 cells that demonstrated an inhibition of proliferation at the PCE concentrations of 100 μg/ml and 50 μg/ml, excessive metabolic activities were reported (max. 155% in MCF12A cells or max. 145% in MCF7 cells). A potential explanation is the already mentioned compensatory secondary effect which was also reported by Abarzua et al. in MCF7 cell lines with similar values (26). Moreover, in the E2 control no stimulatory effect on MCF7 cells was observed. Therefore, PCE-induced enhancement of viability at 100 and 50 μg/ml is probably not related to an ER-mediated process. Other possibilities that increase cellular viability at 100 and 50 μg/ml could be the activation of protective or resistance pathways (elimination of the active compounds by MDR transporters, metabolic detoxification, activation of alternative metabolic pathways). At low PCE concentrations (10 μg/ml-0.01 μg/ml) no eminent metabolic changes were visible, matching the weakly altered proliferation status of the MCF7 and MCF12A cells.

Only one other study investigating the phytoestrogen effects of *Petroselinum crispum* on MCF7 cell lines exists (16) where the influence of parsley leaf extracts and other isolates on MCF7 breast cancer cell lines was investigated. The methanol extract showed progesterone-like properties associated with increased proliferation rates of up to 156% (at a concentration of 10 μg/ml). However, the cell proliferation was not measured by BrdU but only with the MTT assay. It reported similar MTT values (155% at a concentration of 100 μg/ml in MCF12A cell cultures). However, it remains unclear to what extent the cellular metabolic activity is linked with the proliferation rate.

In all assays, estrogen was used as a positive control. In both cell lines it demonstrated no significant cytotoxicity and proliferation compared with the negative control. Previous works using the same cell lines demonstrated similar results.
It is likely that both receptor subtypes (ERα/ERβ) are activated by E2, whereby ERβ intracellularly suppresses the proliferative effect of ERα. Thus the ratio of the expression of ERα/ERβ would be decisive for the different proliferation patterns of the cells. Immunohistochemistry analysis showed that both ERα and ERβ are present on cells (Figure 1). Looking at the images, it is evident that the ERβ expression is weaker but likely strong enough to inhibit ERα mediated cell proliferation.

TAM, which was used as a negative control is a SERM used for the treatment of hormone-sensitive breast cancer for already more than twenty years. It acts as a competitive inhibitor or partial agonist on the ER. On breast cancer cell lines it has an inhibitory effect (29). Correspondingly, a high cytotoxicity and a low metabolism and proliferation were observed in both cell lines treated with TAM.

Previous results demonstrated that PCE has anti-carcinogenic properties. The question of whether and to what extent phytoestrogens are involved cannot be answered precisely. For this reason, mass spectrometry was performed which provided information on the different extract components. In order to determine the efficiency of the extraction method used based on the Luyengi et al. study, a sample of 5 mg raw material (PC) was analyzed in addition to the extract sample.

Mass spectrometry of PCE and PC demonstrated a loss of carbohydrates, monolignols, and nitrogen-containing compounds as well as free amino acids in PCE compared to PC. Except for the monolignols these compounds are not probable constituents of phytoestrogens. An increase in concentration was registered in the groups of lipids, isoprenoids, lignindimeres, lignans and other polyphenols. Particularly the latter three groups are known to have estrogenic effects can be found in the group of lipids: free phytoster estrogen compounds in the PCE. The isoprenoids group contains sterols such as cholesterol (animal) and ergosterol (fungi/protozoa). Other metabolites can form steroids or isoprenoids, lignindimeres, lignans and other polyphenols. The isoprenoids group contains sterols such as cholesterol (animal) and ergosterol (fungi/protozoa).

Particularly the latter three groups are known to have estrogenic activity. This leads to a total sum of 16.6% phytoestrogen compounds in the PCE. The isoprenoids group contains sterols such as cholesterol (animal) and ergosterol (fungi/protozoa). Other metabolites can form steroids or isoprenoids, lignindimeres, lignans and other polyphenols. Particularly the latter three groups are known to have estrogenic activity. This leads to a total sum of 16.6% phytoestrogen compounds in the PCE. The isoprenoids group contains sterols such as cholesterol (animal) and ergosterol (fungi/protozoa). Other metabolites can form steroids or isoprenoids, lignindimeres, lignans and other polyphenols.

Whether this apparent anti-carcinogenic effect of PCE can be solely attributed to its phytoestrogens requires complementary investigations. As a possible approach to determining the role of hormone receptor mediated cell response, PCE could be tested on malignant and benign ER-negative cells (e.g. BT-20/MCF-10A). Additional control substances were identified, of which five possess proven anti-estrogenic properties: apigetrin, apin, diosmetin, kaempferol, 6-acetylapiin (all from the group of flavone glycosides, which also include the strong growth inhibitors genistin and daidzein). Furthermore, an increase in uterine weight of ovariectomized mice fed with the parsley leave extract was observed, which suggests progesterone like growth-promoting effect.

This work proved that PCE causes anti-carcinogenic effects on MCF7/MCF12A cell lines. Growth inhibitory potency of parsley root extract (PCE) on MCF7 mammary tumor cells at non-toxic concentrations (up to 100 μg/ml) was reported. Complementary observation of a less marked inhibition on related MCF12A benign cells suggests an ER-mediated process. Whether this apparent anti-carcinogenic effect of PCE can be solely attributed to its phytoestrogens requires complementary investigations. As a possible approach to determining the role of hormone receptor mediated cell response, PCE could be tested on malignant and benign ER-negative cells (e.g. BT-20/MCF-10A). Additional control substances were identified, of which five possess proven anti-estrogenic properties: apigetrin, apin, diosmetin, kaempferol, 6-acetylapiin (all from the group of flavone glycosides, which also include the strong growth inhibitors genistin and daidzein). Furthermore, an increase in uterine weight of ovariectomized mice fed with the parsley leave extract was observed, which suggests progesterone like growth-promoting effect.
